2017 级弘毅班编译原理课程设计第 6 次编程作业 (the typing of TLC)

1 Introduction

Our goal is the effective implementation of the programming language TLC (Tiny Lambda Calculus) by using the closure.

Lambda calculus is a formal system in mathematical logic and computer science for expressing computation by way of variable binding and substitution (see https://en.wikipedia.org/wiki/Lambda_calculus).

It is computation model of Functional Programming (see L. Paulson's lecture lambda.pdf, or my lecture lambda_lecture.pdf, and try lambda reducer at http://www.itu.dk/people/sestoft/lamreduce/index.html).

1.1 Specification of the language TLC

the syntax of TLC can be described as:

where @x.M is the abstraction (instead of " λ " in lambda calculus for input). M N is the application. the conditional construct is specially added for the lazy evaluation of the conditional lambda terms (see https://en.wikipedia.org/wiki/Lazy_evaluation). let X = M is so called let-binding which binds the variable X with lambda term M. so any free occurrence of X in next context will referred to M. the application is left associative. and the precedence from low to high is: conditional construct, abstraction and application.

see lexer.1 and grammar.y in detail.

1.2 Abstract syntax trees

We use De Brujin index for the AST, it will replace the binding variable by the binding depth. Ex. @x.@y.x is @x.@y.2, @z.(@y.y(@x.x))(@x.z x) is @z.(@y.1(@x.1))(@x.2 1) (see Figure 1). It will be the key to access the closure environment in the implementation. the free occurence of variable is strictly forbidden in TLC.

1.3 Binding Deepth

to find the binding deepth, we use the static stack char *name_env[MAX_ENV] with the cursor int current (tree.c) to store the abstraction level. each time enter AST with ABS node, we push the abstraction name in the stack, increase current for the next, and popup by decreasing current after leave the abstraction body. each time a variable encountered in the abstraction body, find_deepth() will return the number of the deepth in stack when first occurrence is found, see Figure 2.

```
int find_deepth(char *name)
{
  int i = current - 1;
  while (i + 1) {
    if (strcmp(name, name_env[i]) == 0) return current - i;
    i--;
  }
  printf("id %s is unbound!\n", name);
  exit (1);
}
```

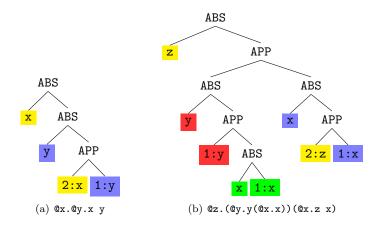

Figure 1: AST with binding deepth (the first number of ID node)

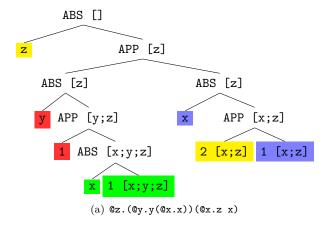

Figure 2: Binding deepth

1.4 Primitive operations and let-bindings

in fact, let-bindings is a syntactic sugar of abstraction and application. so

```
let I = @x.x;
I 3;
```

can be interpreted as (@I.(I 3))(@x.x).

So we will store all names of let-bindings in name_env[].

the arithmetic operations can be treated as predefined let-bingding's name, name_env[] is prestored the following prefined functions and current initialized with 6 (see grammar.y):

```
char *name_env[MAX_ENV] = {"+", "-", "*", "/", "=", "<"};
int current = 6;</pre>
```

to the above binary operators work correctly in λ -calculus, its should interpret as @x.@y.op x y, that is prefix notations! so we will write + * 2 3 4 instead of 2 * 3 + 4. hence

```
+ * 2 3 4
```

will be parsed as ((((+:6)(*:4))2)3).

when the following statement is parsed:

```
let I = @x.x;
```

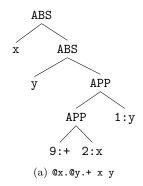

Figure 3: AST of PLUS

I will be stored in name_env[current]. and we also store the AST of @x.x in the global AST *ast_env[MAX_ENV] (all defined in grammar.y) for the further uses. After I parsed, name_env and ast_env will be:

```
name_env[MAX_ENV] = {"+", "-", "*", "/", "=", "<", "I"}
ast_env[MAX_ENV] = {NULL, NULL, NULL, NULL, NULL, Ox.(1:x)}
if we declare PLUS by input:
let PLUS = @x.@y. + x y;
the parser will generate the (@x.(@y.(((+:9)(x:2))(y:1)))). see Figure 3. In fact, after the parser
enter the abstraction body + x y, name_env[] will be:
name_env[MAX_ENV] = {"+", "-", "*", "/", "=", "<", "I", "x", "v"}
so find_deepth("+") will return 9, find_deepth("x") = 2, and find_deepth("y") = 1.
after finish parsing, name_env[] changed to:
name env[MAX ENV] = {"+", "-", "*", "/", "=", "<", "I", "PLUS"}
if we continue define PLUS2 by input:
let PLUS2 = 0x.0y + x 2;
the parser will generate the (@x.(@y.(((+:10)(x:2))(y:1)))). please remark that the binding deepth
of + changed to 10 (see Figure 4). this is because the parsing of PLUS2 is based with the new stack top
"PLUS" of name_env[], the the relative place of "+" is increased by 1.
after PLUS2, name_env[] changed to:
name env[MAX ENV] = {"+", "-", "*", "/", "=", "<", "I", "PLUS", "PLUS2"}
```

1.5 two meanings of "="

the operators "+", "-", ..., "=" will be recognized as normal ID with their binding deepth. but "=" is also used as a single character token '=' in the let-bingding, like "let I = ...". To tell lexer return different tokens when '=' is scanned, we use a global int is_decl (defined in grammar.y), and add a middle action in the decl production to active is_decl.

```
decl : LET {is_decl = 1; } ID '=' expr ';' {...}
and desactive it after return '=' in lexer.l:
"=" {
      char *id;
      if (is_decl) {is_decl = 0; return '='; }
      id = (char *) smalloc(yyleng + 1);
      strcpy(id, yytext);
      yylval = make_string(id);
      return ID;
}
```

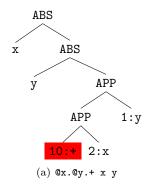

Figure 4: AST of PLUS2

1.6 output

We use the LATEX graphic system tikz/pgf (https://sourceforge.net/projects/pgf/) and tikz-qtree (https://ctan.org/pkg/tikz-qtree) to illustrate AST. printtree(AST *) transforms the AST to LATEX commands and store it in the file expr.tex which is the included file of exptree.tex. "pdflatex exptree.tex" generates the pdf of the AST (see exptree.pdf).

1.7 TODO

Completing grammar.y file to generate the AST for each lambda expression input, and output the AST to the file expr.tex by call printtree(AST *). you can use lambda expression in library.txt to test your program.

please send grammar.y as attached file to mailto:hfwang@whu.edu.cn?subject=ID(05) where the ID is your student id number.

-hfwang November 4, 2019

2 Typing

Well-typed programs cannot go wrong — Robin Milner

(see https://en.wikipedia.org/wiki/Type safety)

2.1 Syntax-directed type synthesiser

As we know, if we admit the "x x" in lambda term, this will cause the Russell's paradox (see L. Paulson's lecture "Foundation of Functional Programming" (PP. 23). to avoid this paradox, we can annotate each lambda term with a type, and if such type can't be established, the term will be rejected.

as example, the first "x" of "x x" should be a function type of form " $A \rightarrow B$ " (A and B are any sets, we call them *type variables*). if it can be applied by an argument, the second "x" must be the same type of the domain of first x, that is A. (see https://en.wikipedia.org/wiki/Simply_typed_lambda_calculus or Pierce's Book "Types and Programming Languages", Ch. 9: Simply Typed Lambda-Calculus). so the type constraint is the equation of type:

$A = A \rightarrow B$

where A is type variable in the type set defined recursively as:

- 1. type constant int is a type.
- 2. X, Y, Z, \ldots , the alphabets of type variable are the type.

3. if A and B are any type, then A \rightarrow B is a type. (so X \rightarrow X, X \rightarrow Y, (X \rightarrow Y) \rightarrow Z,..., are types).

because type variable A appears in right side of the above equation, we have not solution for it.

but the lambda term (@x.x)(@x.x) can be type as $X \to X$. the first (@x.x) (denoted by alpha) can be type as $(A \to A)$ and the second (@x.x) (denoted by beta) can be typed as $(B \to B)$. for the term "alpha beta" have sense, the term alpha must have type function with domain $B \to B$, so the type equation is:

```
A = B \rightarrow B
so A = C \rightarrow C and B = C is the solution.
```

and the *domain* type (left side of the arrow) of alpha is $C \to C$, and the type of (@x.x)(@x.x) is the type of the *range* (right side of the arrow) of alpha, so $C \to C$. Remark the type variable may be changed to any other type.

the above equation has infinite solution like:

```
A = (D \rightarrow D) \rightarrow (D \rightarrow D) and B = D \rightarrow D

A = ((D \rightarrow D) \rightarrow D) \rightarrow ((D \rightarrow D) \rightarrow D) and B = ((D \rightarrow D) \rightarrow D)
```

but all the above solution can be obtained by the substitution of C in the first solution. the first solution is so called *most general*.

the difference of the above 2 term (x x) and (@x.x)(@x.x) is the 2 occurrence of x in the first one are the same x. but the second are not the same.

Our goal is establish the most general type of any given lambda term if it has, or announce the type error if not. the method is *syntax-directed type synthesis*.

2.2 step by step of type synthesis

the type structure is defined in type.h as:

```
typedef enum { Typevar = 1, Arrow = 2, Int = 3 } Type_kind;
  /* for type tree node */
typedef struct type {
  int index; /* for coding type variable */
  Type_kind kind;
  struct type * left, *right;
} Type;
typedef Type * Type_ptr;
typedef struct type_env{
  int redirect; /* for unification use */
  Type_ptr type; /* pointer to the type tree structure */
} Type_env;
typedef Type_env * Type_env_ptr;
extern Type_ptr global_type_env[MAX_ENV];
  /* like name_env[] and ast_env[], global_type_env[]
     will store the type for the declared lambda term */
```

1. each type variable and arrowtype are coded with a unique index when they are created (see make_vartype() and make_arrowtype() in type.c).

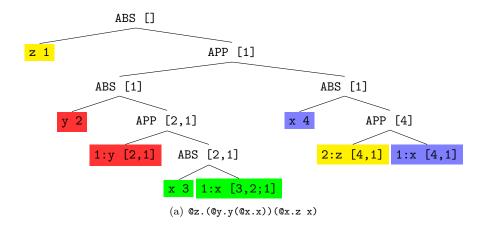

Figure 5: Binding deepth for retrieve the type

- 2. store each type in the typing environment Type_env type_env[MAXNODE] (see type.c), and any type of the index i will store in type_env[i].
- 3. with the De Brujin index (see 1.2), the bounded variable in the body of abstraction is represented by the binding deepth. to access the corresponding type, we can use a stack, just like name_env[] of build the AST. each time enter the abstraction body, the corresponding type of the abstraction variable is push to stack, the type of the variable encountered in the body, is just the n-th element from the top of the stack, where n is the binding deepth. in Figure 5, the preorder tree traversal of AST generate a serie of new type variable (indexed from 1 to 4 for each abstraction, and push it in the stack when enter the abstraction body. for the x in the subterm @x.x, the binding deepth is 1, so the first element (that's 3) from the top stack [3,2,1] (stack top is on the left) is the corresponding type. for the z in the subterm @x.z x, the binding deepth is 2, so the second element (that's 1) from the top stack [4,1] is the corresponding type.

we can simply use a static list just like name_env[] for AST, but for warm-up our next misson (the evaluation of λ -calculus), we will separate the stack into 2 parts: the static part global_type_env[] for the let-binding's names, and dynamic part Var_list abs for the variables of abstraction of the current lambda term in typing. so abs is the extension of the stack. Example 5 will explain how access them.

```
typedef struct varlist {
  char *var_name;
  struct varlist * next;
} Var_list;
typedef Var_list * Var_list_ptr;
```

Notation: in the following, an entry type_env[n] is denoted as n(redirect, type), where n is the type index, redirect is either n or the index of the *redirect* type (see below), type is either n (type variable), either int (type constant), or (x -> y) (arrow), like

```
1(1, (3 \rightarrow 4))
```

Example of type_env[]

```
type_env[] = [0(0,int), 1(1,(3 \rightarrow 4)), 2(2,2), 3(2,3), 4(4,4)]
```

where 3(2,3) means type variable 3 is redirect to 2.

we denote M = T if the lambda term M has the most general type T.

the global environments are setting as:

```
name_env[] = {"+", "-", "*", "/", "=", "<"}
global_type_env[] = [0(int->(int->int)), 1(int->(int->int)), 2(int->(int->int)),
                      3(int->(int->int)), 4(int->(int->int)), 5(int->(int->int))]
current = 6  /* stack top + 1 */
the type constant int always has the index 0.
Each time typing a lambda term, type_env[] will be set to
type_env[] = [0(0,int)]
nindex = 1 /* next index for type variable */
its can be done by
void init_type_env()
  int i = 0;
  type_env[0] = &inttype_entry;
  type_env[0] -> type = & inttype;
  while (i < INIT_POS) {</pre>
    new_env();
    global_type_env[i] =
      storetype(make_arrowtype(&inttype, make_arrowtype(&inttype, &inttype)));
    /* int -> (int -> int) */
    i++;
  }
  return;
}
```

We will use a serie of the examples to stepwise the typing processus by the **recursive tree traversal** of AST.

2.2.1 Example 1: @x.@y.x y (MN: M is a type variable)

The **preorder tree traversal** of AST will compute the stack of abstraction for each AST node. We only setpwise the **postorder traversal** of typing.

```
step 1
top = 8
                /* the stack top index = current + lenght(abs) */
abs: [2,1]
               /* the stack of abstraction */
type_env[] = [0(0,int), 1(1,1), 2(2,2)]
(x:2) = 1
               /* obtain by get 2-th from top of abs */
setp 2
top = 8:
abs: [2,1]
type_env[] = [0(0,int), 1(1,1), 2(2,2)]
(y:1) \mid == 2 /* obtain by get 1-th from top of abs */
step 3
top = 8:
abs: [2,(3 \rightarrow 4)]
type_env[] = [0(0,int), 1(1,(3 \rightarrow 4)), 2(2,2), 3(2,3), 4(4,4)]
((x:2)(y:1)) \mid == 4
```

if the term x y has sense, the x must have the arrow type, but isn't the case. fortunately, x is a type variable, it can be change to any type. function $get_instance(Type_ptr)$ will do that:

```
Type_ptr get_instance(Type_ptr type_tree)
{
   Type_ptr p = final_type(type_tree);
     /* p must be a no redirect type, see below */
   p -> kind = Arrow;
   p -> left = make_vartype(0, 0);
   p -> right = make_vartype(0, 0);
   return p;
}
```

it rewrites the type of the index 1 to an arrow type. and generate 2 type variables of index 3 and 4. so after get_instance(), x is changed to type (3 -> 4). and y is of type 2. to the application x y have the sense, the domain type 2 of x and type 3 of y must be the same. We say they should be unified. we can do it simply by changing 3 to 2. but the problem is that all typing environment which refers 3 must be changed to 2. that is hard job (search all type_env[], replacing the index of 3 with 2. just like update the primary key in the database, you must alter all foreign keys that refer the updated primary key)! To simplify this tedious job, we just redirect the entry of 3 in type_env[] from itself (3) to 2. so we have 3(2,3) in type_env[] where the first component change from 3 to 2 (points to 2). this work can be done by the side-effect function unify_leaf() (it will change the typing environment, after redirection, abs is [2,(3 -> 4)]).

```
void unify_leaf(Type_ptr t1, Type_ptr t2)
{
  int index1 = (t1 -> index);
  int index2 = (t2 -> index);

  if (index1 != index2) {
    type_env[index1] -> redirect = index2;
  }
  return;
}
```

a type variable n(m, t) in $type_{env}[]$ is called final iff n == m. ifnot we call it non-final. int final_type() will across the redirect chain to get the final type. be careful, each time access the type node during the unification prossuss, you must retrieve the final type.

```
int final index (int index)
{
  int i = index;
  if (type_env[i] == NULL) return -1;
  if ( type_env[i] -> type -> kind == Arrow )
    return i;
  if (i == (type_env[i] -> redirect))
    return i;
  return final_index(type_env[i] -> redirect );
/* return final type node for a giving Typevar node */
Type_ptr final_type(Type_ptr t)
{
  int i;
  i = final_index(t -> index);
  if (i == -1) return NULL;
  return type_env[i] -> type;
step 4
top = 7:
abs: [(3 -> 4)]
```

```
type_env[] = [0(0,int), 1(1,(3 \rightarrow 4)), 2(2,2), 3(2,3), 4(4,4), 5(5,(2 \rightarrow 4))]
(@y.((x:2)(y:1))) |== (2 \rightarrow 4)
```

y is of type 2, and x y is of type 4, the abstraction of @y.x y will be typed as an arrow type with a new generated index 5.

step 6

printtype(Type_ptr) will recode the final type variable to A - Z, so 2 as A, 4 as B, then output

```
(0x.(0y.((x:2)(y:1)))) \mid == ((A \rightarrow B) \rightarrow (A \rightarrow B))
```

as an arrow type with a new generated index 6.

step 7

after the typing processus finished, all type that we dynamically allocated must be freed. because every type we maked has an index in type_env[], so we can free all of them easily without any memory leak by

```
void new_env(void)
{
  int i;
  for (i = 1; i < nindex; i++) {
    sfree(type_env[i] -> type);
    sfree(type_env[i]);
    /* redefine free as sfree (in emalloc.c) for
        gprofile the call frequences of free() */
  }
  for (i = 0; i < order; i++)
    index_order [i] = 0;

nindex = 1;
  order = 1;
  step = 0;
}</pre>
```

2.2.2 Example 2: @x.(@x.@y.x y) x (MN: M is arrow and N is type variable)

the first 5 steps are the same as Example 1 with all indexes increased by 1.

```
\frac{\text{step 5}}{\text{top = 7:}}
\text{abs: [1]}
\text{type\_env[] = [0(0,int), 1(1,1), 2(2,(4 \rightarrow 5)), 3(3,3), 4(3,4), 5(5,5), 6(6,(3 \rightarrow 5)),}
7(7,((4 \rightarrow 5) \rightarrow (3 \rightarrow 5)))]
(@x.(@y.((x:2)(y:1)))) |== ((4 \rightarrow 5) \rightarrow (3 \rightarrow 5))
\text{step 6}
```

```
top = 7:
abs: [1]
type_{env}[] = [0(0,int), 1(1,1), 2(2,(4 -> 5)), 3(3,3), 4(3,4), 5(5,5), 6(6,(3 -> 5)),
                 7(7,((4 \rightarrow 5) \rightarrow (3 \rightarrow 5)))]
(x:1) \mid == 1
step 7
top = 7:
abs: [1]
type_{env}[] = [0(0,int), 1(2,1), 2(2,(3 -> 5)), 3(3,3), 4(3,4), 5(5,5), 6(6,(3 -> 5)),
                 7(7,((3 \rightarrow 5) \rightarrow (3 \rightarrow 5)))]
((0x.(0y.((x:2)(y:1))))(x:1)) \mid == (3 \rightarrow 5)
in this time, the function ((@x.(@y.((x:2)(y:1)))) of the application is already an arrow type ((4 ->
5) -> (3 -> 5)) where (4 -> 5) is of the index 2, the argument is type variable 1, we can just redirect
1 to unify the domain type of the arrow and the argument type. so we have the side-effect 1(2,1) in
type_env[].
void unify_leaf_arrow(Type_ptr leaf, Type_ptr t)
  int index = leaf -> index;
  type_env[index] -> redirect = t -> index;
  return;
step 8
top = 6:
abs: []
type_{env}[] = [0(0,int), 1(2,1), 2(2,(3 -> 5)), 3(3,3), 4(3,4), 5(5,5), 6(6,(3 -> 5)),
                 7(7,((3 \rightarrow 5) \rightarrow (3 \rightarrow 5))), 8(8,(1 \rightarrow (3 \rightarrow 5)))]
(0x.((0x.(0y.((x:2)(y:1))))(x:1))) == (1 \rightarrow (3 \rightarrow 5))
remark that the domain type 1 of 8(8,(1 -> (3 -> 5))) is non-final, the redirect final type is 2(2,(3
-> 5)). so
step 9
(@x.((@x.(@y.((x:2)(y:1))))(x:1))) \mid == ((A \rightarrow B) \rightarrow (A \rightarrow B))
2.2.3 Example 3: (@x.@y.x y) (@x.x) (MN: M and N are both arrow)
the first 5 steps is the same as Example 1.
step 5
top = 6:
abs: []
type_{env}[] = [0(0,int), 1(1,(3 -> 4)), 2(2,2), 3(2,3), 4(4,4), 5(5,(2 -> 4)),
                 6(6,((3 \rightarrow 4) \rightarrow (2 \rightarrow 4)))]
(0x.(0y.((x:2)(y:1)))) \mid == ((3 \rightarrow 4) \rightarrow (2 \rightarrow 4))
step 6
top = 7:
type_{env}[] = [0(0,int), 1(1,(3 \rightarrow 4)), 2(2,2), 3(2,3), 4(4,4), 5(5,(2 \rightarrow 4)),
                 6(6,((3 \rightarrow 4) \rightarrow (2 \rightarrow 4))), 7(7,7)]
(x:1) \mid == 7
step 7
```

this time, the argument of function is also function (7 -> 7) which should be unified with (2 -> 4). the unification can be done by unify both domain type and range type of the arrow. unify(2, 7) is the case unify_leaf() which redirect 2 to 7. unify(4, 7) redirect 4 to 7 also.

```
\underline{\text{step } 9}
```

```
((0x.(0y.((x:2)(y:1))))(0x.(x:1))) \mid == (A \rightarrow A)
```

2.2.4 Example 4: 0x.x x

```
step 1
top = 7:
abs: [1]
type_env[] = [0(0,int), 1(1,1)]
(x:1) = 1
step 2
top = 7:
abs: [1]
type_{env}[] = [0(0,int), 1(1,1)]
(x:1) = 1
step 3
top = 7:
abs: [(2 -> 3)]
type_env[] = [0(0,int), 1(1,(2 \rightarrow 3)), 2(2,2), 3(3,3)]
((x:1)(x:1)) == NULL
type A and type (A -> B) can't be unified!
```

the function type is a type variable 1. $get_instance(1)$ rewrite to an arrow. the side-effect change the argument type (second x) to the same arrow. unify(2, 1) is the case $unify_leaf_arrow(2, 1)$, but if we redirect 2 to 1. but 2 is in type 1(1, (2 -> 3)). it's not typable this will also cause the cyclic chain of redirection. it is strictly forbidden. $is_occur_node(2, (2 -> 3))$ checks if such case. if the occurrence take place, report typing error and return NULL.

```
int is_occur_node(int index, Type_ptr type_tree)
{
  int i = index;
  if (type_tree == NULL) return 1;

switch (type_tree -> kind) {
  case Typevar:
    return type_env[type_tree -> index] -> redirect == i;
  case Arrow:
    /* left and right may be not final!!! */
```

```
return is_occur_node (i, final_type(type_tree -> left)) ||
    is_occur_node(i, final_type(type_tree -> right));
case Int:
    return 0;
}
```

2.2.5 Example 5: let MY = @x.@y.x y; (let-binding)

because let-binding is the syntactic sugar of the named term. like AST's name_env[], we will use global_type_env[] store the type of the binding's name MY. but the difference is that the type index stored in global_type_env[] should be rearranged.

the first 5 steps is the same as Example 1.

```
\frac{\text{step 5}}{\text{top = 6:}}
\text{top = 6:}
\text{abs: []}
\text{type_env[] = [0(0, \text{int}), 1(1, (3 \rightarrow 4)), 2(2, 2), 3(2, 3), 4(4, 4), 5(5, (2 \rightarrow 4)), 6(6, ((3 \rightarrow 4) \rightarrow (2 \rightarrow 4)))]}
(0x.(0y.((x:2)(y:1)))) \mid == ((3 \rightarrow 4) \rightarrow (2 \rightarrow 4))
\text{step 6}
```

We will store the name MY in name_env[6] and the AST (@x.(@y.((x:2)(y:1)))) in ast_env[6], and the type in global_type_env[6]. if the next lambda term referes the MY, we should restore the type of MY in type_env[]. storetype(Type_ptr t) will reindex the arrow type with 0 and the final type variable from 1 to n if the type tree has n different leaves.

```
/* generate type_env independant type tree */
Type_ptr storetype(Type_ptr tree)
  if (tree == NULL) return;
  switch ( tree -> kind ) {
  case Int: return &inttype;
  case Typevar: {
    int i = final index(tree -> index);
    Type_ptr t = type_env[i] -> type;
    switch (t -> kind) {
    case Int: return &inttype;
    case Arrow:
      tree -> left = t -> left;
      tree -> right = t -> right;
      break;
    default: {
      int offset = find_index(i); /* reindex the type variable */
      Type_ptr tmp;
      if (offset == 0) {
        return &inttype;
      tmp = (Type_ptr) smalloc(sizeof(Type));
      tmp -> index = offset;
      tmp -> kind = Typevar;
      tmp -> left = tmp -> right = NULL;
      return tmp;
    }
    }
  }
```

```
}
{
   Type_ptr tmp = (Type_ptr) smalloc(sizeof(Type));
   tmp -> index = 0;
   tmp -> kind = Arrow;
   tmp -> left = storetype(tree -> left);
   tmp -> right = storetype(tree -> right);
   return tmp;
  }
}
```

so $global_type_env[6] = (1 \rightarrow 2) \rightarrow (1 \rightarrow 2)$, and the cursor current for the next abstraction or let-binding is increased to 7.

2.2.6 Example 6: @x.MY x

it is the same of Example 2, but the subterm MY is let-binding's name. we should access the correct place in global_type_env[6] and restore the type of MY in the current type_env[].

```
\frac{\text{step 1}}{\text{top = 8:}}
\text{abs: [1]}
\text{type\_env[] = [0(0,int), 1(1,1), 2(2,2), 3(3,3), 4(4,(3 \rightarrow 2)), 5(5,(3 \rightarrow 2)),}
\frac{6(6,((3 \rightarrow 2) \rightarrow (3 \rightarrow 2)))]}{(MY:2) \mid == ((3 \rightarrow 2) \rightarrow (3 \rightarrow 2))}
```

MY is of binding deepth 2 which is greater than the length of stack abs, so it is a let-binding's name. because the glolal_env[current - 1] is the extension of stack abs. we can get it by top - 2. get_n_th([1], 2, 8) will restore the type of MY as 6(6,((3 -> 2) -> (3 -> 2))) with new series of indexes from 2 to 6.

```
Type_ptr get_n_th_from_global(int i)
  /* if is the fixed-point combinator, we will
     assign it with the type (A \rightarrow A) \rightarrow A.
     Z, Y and rec is defined in library.txt */
  if (strcmp(name_env[i], "Z") == 0 ||
      strcmp(name_env[i], "Y") == 0 ||
      strcmp(name_env[i], "rec") == 0) {
    return make_rec_type();
  }
 return restoretype(global_type_env[i]);
  /* restoretype will reindex the type variable in new type_env[] */
/* pos is the current top of name_env[] */
/* n is the binding deepth of the lambda variable */
Type_ptr get_n_th(Var_list_ptr list, int n, int pos)
{
  int i = 0;
  /* is a predefined name */
  if ((pos - n) >= 0)
    return get_n_th_from_global(pos - n);
  while (i != n - 1 && list != NULL) {
    list = list -> next;
    i++;
  }
```

```
/* is an abstraction */
  if (i == n - 1 && list != NULL)
    return list -> type_var;
  printf("wrong access global type env\n");
  exit (1);
}
the following steps are as Example 2.
step 2
top = 8:
abs: [1]
type_{env}[] = [0(0,int), 1(1,1), 2(2,2), 3(3,3), 4(4,(3 -> 2)), 5(5,(3 -> 2)),
                6(6,((3 \rightarrow 2) \rightarrow (3 \rightarrow 2)))]
(x:1) = 1
step 3
top = 8:
abs: [1]
type_{env}[] = [0(0,int), 1(5,1), 2(2,2), 3(3,3), 4(4,(3 -> 2)), 5(5,(3 -> 2)),
                 6(6,((3 \rightarrow 2) \rightarrow (3 \rightarrow 2)))]
((MY:2)(x:1)) \mid == (3 \rightarrow 2)
step 4
top = 7:
abs: []
type_{env}[] = [0(0,int), 1(5,1), 2(2,2), 3(3,3), 4(4,(3 \rightarrow 2)), 5(5,(3 \rightarrow 2)),
                 6(6,((3 \rightarrow 2) \rightarrow (3 \rightarrow 2))), 7(7,(1 \rightarrow (3 \rightarrow 2)))]
(0x.((MY:2)(x:1))) \mid == (1 \rightarrow (3 \rightarrow 2))
step 5
(0x.((MY:2)(x:1))) \mid == ((A \rightarrow B) \rightarrow (A \rightarrow B))
2.2.7 Example 7: recursions
the fixed-point combinator (https://en.wikipedia.org/wiki/Fixed-point_combinator) can be pre-
defined as
let Y=0f.(0x.f(x x))(0x.f(x x));
let Z=0f.(0x.f(0y.(x x)y))(0x.f(0y.(x x)y));
because x \times (apply itself) can't be typable. so if we input:
0f.(0x.f(x x))(0x.f(x x));
typing step 1 and top = 9:
abs: [2,1]
type_env[] = [0(0,int), 1(1,1), 2(2,2)]
(f:2) \mid == 1
typing step 2 and top = 9:
abs: [2,1]
type_env[] = [0(0,int), 1(1,1), 2(2,2)]
(x:1) = 2
typing step 3 and top = 9:
abs: [2,1]
type_env[] = [0(0,int), 1(1,1), 2(2,2)]
```

```
(x:1) |== 2
type A and type (A -> B) can't be unified!
typing step 4 and top = 9:
abs: [(3 -> 4),1]
type_env[] = [0(0,int), 1(1,1), 2(2,(3 -> 4)), 3(3,3), 4(4,4)]
((x:1)(x:1)) |== NULL
```

to type the recursive function defined by the fixed-point combinators, we should assign them the type $(A \rightarrow A) \rightarrow A$ so we have:

```
let fact = (Z (@f.@n. (if (= n 0) then 1 else (* n (f (- n 1))) fi)));
it will return
((Z:1)(@f.(@n.if(((=:7)(n:1))0)then1else(((*:9)(n:1))((f:2)(((-:10)(n:1))1))))))
|= (int -> int)
```

this can be done in get_n_th_from_global(int i) by checking if name_env[i] is Y, Z, or rec. if so, just return the above type (see above).

2.3 Church encoding and Type

In mathematics, Church encoding is a means of representing data and operators in the lambda calculus. The data and operators form a mathematical structure which is embedded in the lambda calculus.

The Church numerals are a representation of the natural numbers using lambda notation. The method is named for Alonzo Church, who first encoded data in the lambda calculus this way (https://en.wikipedia.org/wiki/Church_encoding).

You can see this encoding in library.txt.

1. Church numerals:

```
ZERO |== (A -> (B -> B))

ONE |== ((A -> B) -> (A -> B))

TWO |== ((A -> A) -> (A -> A))

.....

FIVE |== ((A -> A) -> (A -> A))
```

2. Arithmetic operation:

3. Booleans

```
TRUE |== (A -> (B -> A))

FALSE |== (A -> (B -> B))

IF |== ((A -> (B -> C)) -> (A -> (B -> C)))

OR |== (((A -> (B -> A)) -> (C -> D)) -> (C -> D)

AND |== ((A -> ((B -> (C -> C)) -> D)) -> (A -> D))

NOT |== (((A -> (B -> B)) -> ((C -> (D -> C)) -> E)) -> E)

GE |== ((((((((A -> (B -> A)) -> C) -> ((D -> (C -> E)) -> E)) -> (((F -> (F -> G)) -> G)

-> ((H -> (I -> I)) -> J))) -> ((C -> D) -> (F -> J))) ->
```

```
(K \rightarrow ((L \rightarrow (M \rightarrow (N \rightarrow N))) \rightarrow ((O \rightarrow (P \rightarrow O)) \rightarrow Q)))) \rightarrow (K \rightarrow Q))
                 LE |== (A -> ((((((((B -> (C -> B)) -> D) -> ((E -> (D -> F)) -> F)) ->
                                                                         (((G -> (G -> H)) -> H) -> ((I -> (J -> J)) -> K))) -> ((D -> E) -> (G -> K))) ->
                                                                         (A \rightarrow ((L \rightarrow (M \rightarrow (N \rightarrow N))) \rightarrow ((O \rightarrow (P \rightarrow O)) \rightarrow Q)))) \rightarrow Q))
                  EQ |== NULL
                  let LEQ = @m.@n.ISZERO (SUB m n);
                  LEQ = (A \rightarrow ((((((B \rightarrow (C \rightarrow B)) \rightarrow D) \rightarrow ((E \rightarrow (D \rightarrow F)) \rightarrow F)) \rightarrow F)) \rightarrow ((E \rightarrow (D \rightarrow F)) \rightarrow F)) \rightarrow ((E \rightarrow F)) \rightarrow
                                                                                (((G \rightarrow (G \rightarrow H)) \rightarrow H) \rightarrow ((I \rightarrow (J \rightarrow J)) \rightarrow K))) \rightarrow ((D \rightarrow E) \rightarrow (G \rightarrow K)))
                                                                               \rightarrow (A \rightarrow ((L \rightarrow (M \rightarrow (N \rightarrow N))) \rightarrow ((0 \rightarrow (P \rightarrow 0)) \rightarrow Q)))) \rightarrow Q))
                  let EQ1 = @m.@n. AND (LEQ m n) (LEQ n m);
                 EQ1 |== NULL
                 EQ and EQ1 can't be typed!
4. Recursions
                 Y | == NULL
                 Z |== NULL
                 FACT | == NULL
                 SUM | == NULL
                 DIV |= NULL
                 fact |== (int -> int)
                  (C \rightarrow D)) \rightarrow D)) \rightarrow ((((E \rightarrow F) \rightarrow (F \rightarrow G)) \rightarrow
                                                                                 ((E \rightarrow F) \rightarrow (E \rightarrow G))) \rightarrow H)) \rightarrow H)
```

FACT and SUM coding with Church numerals can't be typed, even added the axiom Y |== (A -> A) -> A. fact with lazy if is typable under the axiom. Ackermann function (https://en.wikipedia.org/wiki/Ackermann_function) is typable.

2.4 TODO

2.4.1 Unification algorithm

refer the unification algorithm of Dragon book (PP. 397), finish the side-effect unification algorithm:

```
/* return 1 if unified; return 0 ifnot */
int unify(Type_ptr t1, Type_ptr t2)
{
 t1 = simply(t1);
 t2 = simply(t2);
 if (t1 == NULL || t2 == NULL) {
    printf("null type occur! typing error!\n");
   return 0;
  switch (t1 -> kind) {
  case Int: {
    /* todo */
 }
  case Typevar: {
   /* todo */
 case Arrow: {
   /* todo */
 }
 }
 return 1;
```

2.4.2 the semantic rules of type synthesis

each AST T has 3 attributes:

- 1. T.top: = current + abstraction deepth
- 2. T.abs: the stack of the type of the abstraction.
- 3. T.type: type

the typing will work with the global type_env[], name_env, global_type_env[], nindex, current...

AST	semantic rules				
ROOT	ROOT.abs = [] /* empty stack */				
	ROOT.top = current				
T = CONST n	T.type = int				
T = VAR (n:x)	T.type = get_nth(T.abs, n, T.top)				
T = ABS (x, T1)	<pre>x.type = make_vartype()</pre>				
	T1.abs = add_list(x.type, T.abs)				
	T.type = make_arrow(x.type, T1.type)				
	T1.top = T.top + 1				
T = COND(T1, T2, T3)	T1.abs = T.abs T1.top = T.top				
	T2.abs = T.abs T2.top = T.top				
	T3.abs = T.abs T3.top = T.top				
	<pre>if (T1.type == int && unify(T2.type, T3.type))</pre>				
	T.type = T2.type				
	else T.type = NULL				
T = APP (T1, T2)	/* todo */				
	/* you should included this SDD in the file type.c */				

2.4.3 Typing

the attributes T.abs and T.top are L-attributed. T.type is S-attributed. so we can solve them with recursive tree traversal. Implement the following typing function.

```
Type_ptr typing (Var_list_ptr abs, AST *t, int top)
 Type_ptr tmp; /* for store the return type */
 if (t == NULL) return NULL;
  switch (t \rightarrow kind) {
 case CONST: return make_inttype();
 case VAR: {
    tmp = get_n_th(abs, t -> value, top);
    break;
  case ABS: {
   /* todo */
  case COND: {
  /* todo */
  case APP: {
  /* todo */
 }
 if (yyin == stdin) {
    printf("typing step %d and top = %d:\n", ++ step, top);
```

```
print_abs(abs);
  print_env();
  print_expression(t, stdout);
  printf(" |== "); print_type_debug(tmp); printf("\n");
}
free_list(abs);
  return tmp;
}
```

Be careful: every recursive call of typing() should pass the copy of abs list by call Var_list_ptr list_copy (Var_list_pt).

2.4.4 Memory leaks

You program should have no memory leaks!!! you can test it by input multiple lines:

```
0m.m(0f.0n.n f(f(0f.0x.f x)))(0n.0f.0x.n f (f x));
```

then gprof ./lambda. the difference of smalloc and sfree should be the same like:

ONE INPUT of the above lambda term:

% c	umulative	self		self	total	
time	seconds	seconds	calls	Ts/call	Ts/call	name
0.00	0.00	0.00	602	0.00	0.00	print_type_debug
0.00	0.00	0.00	268	0.00	0.00	smalloc
0.00	0.00	0.00	226	0.00	0.00	sfree

TWO INPUT of the above lambda term:

% с	umulative	self		self	total	
time	seconds	seconds	calls	Ts/call	Ts/call	name
0.00	0.00	0.00	1204	0.00	0.00	<pre>print_type_debug</pre>
0.00	0.00	0.00	470	0.00	0.00	smalloc
0.00	0.00	0.00	428	0.00	0.00	sfree

please send your type.c as attached file to mailto:hfwang@whu.edu.cn?subject=ID(06) where the ID is your student id number.

-hfwang

November 4, 2019
